Abstract: River floodplains in the Netherlands serve as water storage area, while they also have the function of nature rehabilitation area. Floodplain vegetation is therefore subject to natural processes of vegetation succession, which obstructs the water flow into the floodplains and increases the flood risk for the hinterland. Space-based pointable imaging spectroscopy has the potential to quantify vegetation density from a desired view zenith angle. In this respect, hyperspectral pointable CHRIS data were linked to the ray tracing canopy reflectance model FLIGHT to retrieve vegetation density estimates over a heterogeneous river floodplain. FLIGHT enables to simulate top-of-canopy reflectance of vegetated surfaces either in turbid (e.g. grasslands) or in 3D (e.g. forests) mode. By inverting FLIGHT against CHRIS data, the vegetation density parameter leaf area index (LAI) was computed for three main classified vegetation types, 'herbaceous', 'shrubs' and 'forest', and for the CHRIS view zenith angles in nadir, backward (-36°) and forward (+36°) scatter direction. The -36° direction showed most LAI variability within the vegetation types and was best validated, closely followed by the nadir direction. The +36° direction led to poorest LAI retrievals. The class-based inversion process has been implemented into a GUI toolbox which would enable the river manager to generate LAI maps in a semiautomatic way.

1. Introduction

Climate change is expected to have a large impact on water resources and flooding risks of the main rivers in the Netherlands [1]. General circulation models applied on the Rhine river basin predict higher winter discharge and peak flows as a result of increased winter precipitation and earlier snow-melt in the Alps [2,3]. In the past, measures for improvement of river navigation, as well as agricultural development have caused the Rhine to lose its natural meanders while significant parts of the floodplain have been affected by urban development [4,5]. As a result, the capability of the river system to accommodate peak flows has been reduced which leads to increased flooding risks for the floodplains and its hinterland [6].

During the last decades, the water discharge capacity of the river system in the Netherlands has been increased by lowering and widening of the floodplains, removal of groynes and hydraulic obstacles in the floodplains and by excavation of secondary channels [7,8]. Concomitantly, these newly developed river floodplains also serve as nature restoration areas, where succession of vegetation leads to highly valued ecosystems [9]. However, floodplain vegetation causes resistance to the water flow within the river floodplains [10]. Because of the complex structure of floodplain vegetation and the accumulation of material caused by sedimentation processes, flood flow velocities decrease and the water surface increases during flooding events [11]. For assessment of current and future river management scenarios in low land rivers like the Rhine in the Netherlands, information on the spatially complex structure and density of floodplain vegetation is a key issue [12].

To intervene with the spontaneous vegetation succession, the concept of Cyclic Floodplain Rejuvenation (CFR) has been introduced for management of the Rhine river system [13]. CFR implies periodic anthropogenic disturbance of floodplain ecosystems through removal of climax vegetation to create more space for water. To support this approach, regular monitoring of the spatial distribution and structure of floodplain vegetation is required for estimating the hydraulic roughness within the floodplain. Hydraulic roughness indicates to what extent the water flow is obstructed and is directly related to vegetation height and density, rigidity of the stems and the presence of leaves [12,13]. For the rivers Rhine and Meuse in the Netherlands, ecotope maps are used for determining hydraulic roughness values of the vegetation, resulting in one roughness value per ecotope object. Currently, ecotope maps are based on digital false colour aerial photographs and ancillary *in situ* data on flood

68   duration, management, water depth and morphodynamics [14]. However these techniques are tedious

69   and time-consuming and no information on spatial variability of vegetation density within the ecotopes

70   is provided.

71   Alternatively, satellite based Earth observation (EO) can play a major role by providing a

72   quantifiable, spatially-explicit and replicable technique for monitoring and assessing the magnitude of

73   vegetation density. With optical EO data, vegetation properties can be characterised into a few

74   essential structural variables such as leaf area index (LAI), defined as the total of one-sided area of

75   leaves per area (m^2/m^2) [15]. Within this approach for approximating hydraulic roughness, LAI

76   provides continuous vegetation density information at the pixel level. Implementing LAI in hydraulic

77   roughness calculation schemes may bypass the need for many elaborative field measurements [16].

78   The retrieval of LAI from EO data is often based on empirical relationships between spectral

79   vegetation indices and ground-based measurements [17,18]. These relationships work well under

80   particular viewing and illumination geometry and for specific vegetation phenology, but they tend to

81   produce inaccurate results when applied over a broad range of land cover types and optical and

82   geometric conditions encountered in satellite images. Canopy reflectance is the result of several

83   intricately coupled physical processes and it is therefore difficult to estimate the influence of a single

84   parameter from experimental data (e.g., [19]). Contrary to empirical approaches, radiative transfer

85   (RT) models take the physical features of a plant canopy into account and are therefore more realistic

86   in describing the interaction of solar radiation with vegetation components. From a radiative transfer

87   point of view, a vegetation canopy composed of components like leaves, stems, flowers, etc., can be

88   considered as an ensemble of scattering elements, bounded by a background, e.g., soil [20]. A physical

89   RT model describes the transfer and interactions of solar radiation inside such a canopy and thus

90   provides an explicit link between the structural characteristics of vegetation scattering elements and the

91   canopy reflectance. In these RT models the spectral signal is a function of canopy geometry, defined

92   by canopy structural variables such as LAI, leaf angle distribution and fractional vegetation cover,

93   optical leaf and soil properties, illumination and viewing geometry [21-23]. LAI is a typical state

94   variable of RT models, describing the density of the scattering elements. In turn, these biophysical

95   variables can be extracted from RT models through model inversion.

96   Among RT models, FLIGHT [24] is a physical three dimensional (3D) ray tracing model based on

97   Monte Carlo simulations of photon transport. FLIGHT is accurate in mimicking vegetation structure: it

98   simulates interactions between geometric primitives representing the canopy and solar radiation on a

99   photon-by-photon basis. Inversion of the model against measured reflectance data allows retrievals of

100   LAI at the sensor sub-pixel scale.

101   Apart from the expected enhancement of the physical RT modelling approach for retrieval
102 accuracy, additional gains are to be expected with the use of pointable sensors. Canopy reflectance
103 measurements acquired under different observation angles have shown to yield unique information
104 pertaining to vegetation structure [25-31]. The presence of shadows in the canopy forms an important
105 argument for exploring pointable data because the shadowing effect in vegetated surfaces will result in
106 enhanced reflectance in the backscatter direction and reduced reflectance in the forward scatter
107 direction of the principal plane [32]. Hence, observed variation in reflectance anisotropy is a function
108 of sun-target-sensor geometry and the composition and structure of the vegetation cover. Therefore,
109 the combined use of RT methods with pointable imaging spectroscopy data may lead to a more robust
110 approach to map the complex floodplain vegetation structure and density from space.

111   The ESA's Compact High Resolution Imaging Spectrometer (CHRIS) on board the Project for On
112 Board Autonomy (PROBA) satellite is a pointable, imaging spectroscopy sensor that was designed as a
113 technology demonstrator [28]. CHRIS is capable of measuring reflected radiation in the visible and
114 near-infrared (NIR) wavelengths from five different viewing angles by pointing five times to the same
115 target during a single overpass. The sensor can be configured in different imaging modes with specific
116 spectral and spatial settings. Especially, mode 3 is appropriate for vegetation structure mapping as it is
117 characterized by both a high spatial (~17m) and high spectral resolution with 18 bands measuring in
118 the visible and NIR wavelengths from 400 to 1050 nm, thereby covering a region of 13 by 13 km (full
119 swath) [28].

120   Several studies have been performed using pointable CHRIS data combined with an RT modelling
121 approach to derive LAI values for homogeneous vegetation stands in agricultural fields [33-34].
122 FLIGHT has proven to be successful in combination with angular CHRIS data and its use for
123 retrieving vegetation structure because of simulating vegetated surfaces at the same spatial resolution
124 [19,35]. However, research on quantitative vegetation density retrieval in heterogeneous floodplain
125 ecosystems, taking into account different vegetation types such as species-rich grasslands grading
126 towards shrub and tree encroachments, have rarely garnered attention in the scientific literature.

127   In this study we aim at characterizing the vegetation density of a spatially and spectrally complex
128 river floodplain ecosystem using angular CHRIS data. The objective is threefold: *i*) to develop a
129 methodology for physically-based mapping of the density variable LAI of several vegetation types in a
130 river floodplain ecosystem using FLIGHT; *ii*) to explore the added value of the use of the pointable
131 dimension in the applied methodology; and *iii*) to assess the opportunities to upscale the methodology
132 developed for a local floodplain to a complete river section at the regional scale.

133

134

135 **2. Materials and Methods**

136 *2.1. Study site*

137

138   The study site is the floodplain Millingerwaard (51° 84' N, 5° 99' E) along the river Waal, which is

139 the main branch of the river Rhine in the Netherlands (figure 1). Millingerwaard (700 ha) is one of the

140 main floodplains of the nature reserve Gelderse Poort, with a total surface area of 6700 hectare. Within

141 the Netherlands, the Gelderse Poort serves as important riparian corridor within the Natura 2000

142 network of the European Union. Before 1990, Millingerwaard was used as an agricultural area with

143 intensively managed grassland and arable crops (e.g., maize). Starting from 1990, agricultural

144 management was gradually reduced and a nature rehabilitation plan was started. By digging out clay

145 deposits from the topsoil, the old patterns of side streams, natural levees and isles were reconstructed

146 in the landscape. Floodplain vegetation was going through natural succession and a regime of grazing

147 by cattle and horses in low densities was introduced. Current vegetation of the Millingerwaard

148 floodplain consists of mixed patches and ecotones, i.e. transitions between communities with a

149 dominance of grass, herbaceous vegetation, dwarf and tall shrubs, and a large softwood forest [36].

150 Softwood forest in Millingerwaard is dominated by willow trees (*Salix fragilis* and *Salix alba*). The

151 forest canopy has an open structure with dense undergrowth (*Urtica dioica* (stinging nettle), *Arctium*

152 *lappa* (greater burdock)*, Galium aparine* (cleavers)) and open water bodies due to the low elevation

153 and high ground water levels. The non-forest vegetation is characterized by a heterogeneous patchy

154 structure of different vegetation succession stages. Dominant species are *Urtica dioica, Calamagrostis*

155 *epigejos* (wood small-reed), *and Rubus caesius* (dewberries). Finally, a limited number of parcels is

156 still in agricultural use. Vegetation types present in Millingerwaard are representative for the

157 vegetation succession stages of the other floodplains within the Gelderse Poort nature reserve. At this

158 moment, the surface area of agricultural land in the complete Gelderse Poort is relatively high

159 compared to that of the Millingerwaard, however, this will change over the coming decade as

160 agricultural management will be changed to a nature management regime.

161

162

163   **Figure 1.** The study area which is located in the east of the Netherlands, indicated on the CHRIS nadir
164   image in true colour band composition (R: 675.2 nm, G: 551.7 nm, B: 490.5 nm). The red circle
165   represents the river floodplains of Millingerwaard. The black outlined river area overlain on the
166   CHRIS nadir image represents the nature reserve the Gelderse Poort which was used for upscaling of
167   the method.

168
169

170   *2.2. CHRIS data*

171

172   Concomitant pointable CHRIS images for the Millingerwaard and a large part of the Gelderse Poort
173   (figure 1) were acquired on 6 September 2005 in mode 3 under cloud-free conditions around solar
174   noon. Data were available in five different nominal viewing zenith angles (VZA): nadir, ±36º, ±55º.
175   The pointable observations are named as such hereafter. The actual position of the sensor during the
176   satellite overpass is shown in the polar plot of figure 2. Negative viewing angles represent
177   measurements in the backscatter direction, where most sunlit canopy is viewed by the sensor; positive
178   viewing angles represent measurements in the forward scatter direction, where most shadowing effects
179   are present. The solar zenith angle during acquisition was 46º. For the purpose of this research, the
180   images of VZA nadir and ±36º were used, because the ±55º angular images did not cover the
181   Millingerwaard study area.

182

183

184   **Figure 2.** Polar plot showing the actual positions of the 5 angular CHRIS images during acquisition on
185   6 September 2005. The solar zenith angle was 46°, the solar azimuth angle 170°.
186
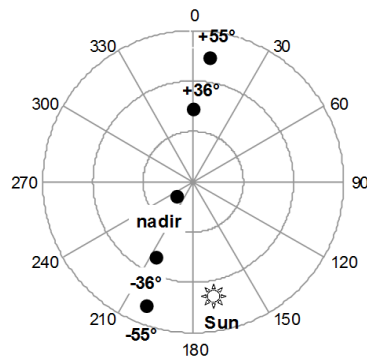

187
188

189   Automatic image registration of the CHRIS nadir and ±36º images was performed according to the
190   method of [37] to reference the three separate images to each other. Geometric correction of these
191   three images was carried out with use of 34 ground control points (GCP's) which were collected from
192   a high spatial resolution (0.5 m) aerial photograph from early spring 2006. Because the CHRIS images
193   were already referenced to each other, the GCP's were taken from the nadir image only and also
194   applied to the ±36º images. A 2nd order polynomial model with nearest neighbourhood resampling
195   technique was used for geometric correction of the three images which resulted in a control point error
196   of 0.31 pixels. Atmospheric correction of the images was performed according to the method described
197   by [38] using the CHRIS-Box software developed as a plug-in for the BEAM toolbox (Brockmann
198   Consult, http://www.brockmann-consult.de/beam).

199

200   *2.3. Land cover classification of CHRIS nadir image*

201

202   Prior to vegetation density retrieval in canopies comprised of a heterogeneous mix of vegetation
203   types, these vegetation types need to be identified so that the RT model can be parameterized
204   accordingly. Such vegetation class-based inversion approach is operationally being done at a global
205   scale to derive MODIS products [39] and was recently introduced by [40] at local scale for precision
206   farming applications. Here, using information from the three observation angles, a map was created
207   that included eight major land cover classes. The vegetated classes consisted of 'bare and pioneer
208   communities', 'grasses and herbaceous vegetation', 'herbaceous and low woody vegetation', 'shrubs',
209   and 'forest'. These classes are in accordance to the class definitions used by [41] that serve as a
210   minimum set to estimate hydraulic resistance for river management purposes. The class 'forest'
211   represents the areas that consist of pixels with tree cover. The classes 'water', 'build up area', and
212   'arable land' were added to be able to classify the whole CHRIS image. A summary of all classes and
213   their main characteristics is listed in table 1, the undertaken steps are shortly explained below.

214

215   **Table 1.** Classes used for classification of the CHRIS image.

216

	Class name	Class characteristics
1	Bare soil & pioneer vegetation	mainly sand
2	Grasses and low herbaceous vegetation	vegetation < 1m
3	Higher herbaceous vegetation	vegetation between 1m and 2m
4	Shrubs	shrubs and trees < 5m
5	Forest	trees > 5m
6	Water	water
7	Build up	streets, houses
8	Arable land	maize

217
218

219   Maximum likelihood (ML) classification was performed on the CHRIS nadir image to classify the
220   identified land cover classes within the boundaries of Millingerwaard (figure 1). First, a training data
221   set was defined on which the classification was based. Regions of interest (ROIs) were selected as
222   training data for each land cover class. The CHRIS nadir image was used to roughly discriminate
223   between classes. Field knowledge and aerial photographs of early spring 2006 were used as reference
224   for selecting ROIs. The principal component (PC)-bands of the stacked images (nadir and VZA ±36º)
225   were very useful to identify sharp boundaries between different land cover classes; because certain PC-
226   band combinations showed bright colourful images which made it easy to distinguish the different land
227   cover types. The selection of ROIs was evaluated by computing ROI separability based on the
228   transformed divergence and Jeffries-Matusita Distance of the whole visible and NIR (VNIR) spectrum
229   from the CHRIS nadir image. The separability values showed that the pair of 'higher herbaceous
230   vegetation' and 'grasses and low herbaceous vegetation' had highly comparable spectral
231   characteristics.

232   The aerial photographs of 2006 were used as basis for selection of data-points to validate the
233   classification result of the major land cover classes. A set of twenty random sample points was selected
234   per class resulting in the selection of 160 points in total. The distance between two points was set to a
235   minimum of 100 m to prevent choosing points located too close to each other. A difficulty with the use
236   of aerial photographs was to differentiate between 'low grasses & herbaceous vegetation' and 'higher
237   herbaceous vegetation'. Based on field knowledge, and the assumption that patches of grasslands with
238   an irregular shape consisted of taller grasses and herbaceous vegetation, those patches were labelled to
239   the class of 'higher herbaceous vegetation'. Finally, classification accuracies and the kappa statistic
240   were calculated for the classified land cover map.

241

242

243   *2.4 FLIGHT model inversion to derive LAI*

244

245   The ray tracing FLIGHT model simulates photon trajectories, starting from a solar source, through

246   successive interactions with the vegetation, to a predetermined sensor viewing angle [24]. The model

247   incorporates the probability of free path, absorption and scattering of photons and accounts for

248   shadowing effect, crown overlapping and multiple scattering between crowns. Within the crown,

249   photons are scattered based on probability density functions. The individual photons are followed until

250   they are either absorbed or exited by the canopy. The model outcome is scene top-of-canopy bi-

251   directional reflectance (BRF) values, the result of a unique stand configuration, solar illumination

252   direction, surface reflection direction and spectral wavelength (λ). FLIGHT can be operated either in

253   1D or 3D mode. In 1D mode, the vegetation canopy is modelled as turbid medium, which can be seen

254   as a layer that contains a mix of different canopy elements which represent the vegetation density

255   characteristics. Vegetation density of a scene is exclusively controlled by LAI. In 3D mode, the

256   vegetation canopy is modelled as a 3D representation of tree crowns, which are idealized by

257   volumetric primitives of defined shapes with associated shadowing effects. Vegetation density within

258   the volumetric primitives is controlled by LAI and the density of the primitives within a scene is

259   controlled by fractional vegetation cover. This 1D/3D flexibility enables to employ a better

260   representation of patchy landscapes, i.e., homogeneous areas can be simulated in 1D mode while

261   heterogeneous areas (e.g., 'forest') can be simulated in 3D mode.

262   The vegetation classes used in the classification were simplified to form a base map for the class-

263   based model inversion. From the five vegetation classes 'bare and pioneer communities'; 'grasses and

264   herbaceous vegetation'; 'herbaceous and low woody vegetation'; 'shrubs'; and 'forest', the vegetation

265   class 'bare soil and pioneer communities' was omitted from further analysis because this class does not

266   have a complex structure thus the influence on the hydraulic resistance can be neglected. The two

267   classes 'low grasses and herbaceous vegetation' and 'higher herbaceous vegetation' which showed a

268   relatively low separability were aggregated into one class of 'herbaceous' vegetation. This led to three

269   distinct vegetation classes 'herbaceous', 'shrubs' and 'forest', for parameterization of FLIGHT. The

270   'herbaceous' and 'shrubs' classes were parameterized in 1D mode because of its continuous horizontal

271   distribution, while 'forest' was parameterized in 3D mode. For each vegetation class, model

272   parameters; leaf, woody and background spectra; and LAI variable ranges were defined and fed into

273   FLIGHT (table 2). Vegetation model parameters were defined based on field measurements and ranges

274   of variables were defined based on findings in literature [42-44]. Leaf reflectance and transmittance

275   spectra were measured with an ASD field spectrometer during a field campaign in 2004. Also tree

276   geometry indicators were measured and are listed in table 2. We assumed that changes in leaf structure

and composition of willow trees (> 20 years old), as present in Millingerwaard, are small within a period of one year, and that therefore the field measurements match the reflectance spectra of leaves of willow trees in 2005. Additional reflectance spectra of various bark and background types were collected in April 2009 with an ASD field spectrometer. The spectra were resampled to the band settings of the CHRIS sensor.

Table 2. FLIGHT model parameters and variables, and input spectra.

Class name	Input spectra		
	Leaf	**Background**	**Bark**
Herbaceous	Calamagrostis epigejos	0.95*forest background + 0.05*sandy soil	
Shrubs	Salix alba	average (water, grass & forest background)	Salix alba
Forest	Salix alba	forest background	Salix alba

Class name	Variables		Fixed parameters		
	Fcover	**LAI (m²/m²)**	**PV**	**Scene**	**Leaf size (m)**
Herbaceous	0.2-1; step: 0.02	0.2-10; step: 0.1 until 5; step: 0.5 until 10	1	1D	0.027
Shrubs	0.2-1; step: 0.02	0.2-10; step: 0.1 until 5; step: 0.5 until 10	0.7	1D	0.02
Forest	0.2-1; step: 0.02	0.2-10; step: 0.1 until 5; step: 0.5 until 10	0.7	3D	0.02

Fixed parameters tree geometry	
Crown shape	ellipsoid
crown radius	3
Centre to top distance	3
Height to first branch:	
Min:	1
Max:	4
Trunk DBH	0.4

Model inversion is required in order to retrieve vegetation characteristics from reflectance data through physically based models [45]. Inversion was accomplished by means of a lookup-table (LUT) approach [46]. The LUT provides a simple way of the inversion of a radiative transfer model and also reduces the computational demand compared to the traditional optimization approach [48,49]. For each VZA and each vegetation class a LUT containing simulated reflectance data was built by means of combining the canopy variables following the steps as provided in table 2. Given the LUT input parameters, FLIGHT subsequently computed the BRF for 18 spectral bands corresponding to the band settings of the CHRIS sensor. The inversion itself was done by first calculating the root mean square errors (RMSE) between each measured reflectance spectrum from the CHRIS nadir and ±36° images and all simulated BRF spectra as stored in the LUT. Because multiple variable combinations may lead to the same spectra (the problem of ill-posedness), the solution applied here is the average of variable

299 combinations found within less than 10% of the lowest RMSE value. The 10% threshold agrees with
300 several studies that attempted to optimize inversion (e.g., [49-51]). As such, LAI values were pixelwise
301 retrieved per vegetation class for the nadir and the ±36° VZAs. Additionally, RMSE residuals were
302 provided to obtain information about the performance of the retrievals. The residuals reveal the
303 closeness of actual spectral observations to that of the simulated spectra in the inversion; lower
304 residual means a better match. This enabled to compare differences in retrieval performances between
305 angles. Finally, for each of the three viewing angles the maps with the class-specific retrievals from the
306 herbaceous, shrubs and forest class were aggregated in order to generate LAI maps for the entire area
307 of Millingerwaard.

308   An essential step in asserting the appropriateness of optical EO measurements to partake in the
309 characterization of vegetation density variables is to seek evidence in the validity of the variables.
310 Validation of LAI measurements were derived from a ground sampling campaign which was carried
311 out in first two weeks of august 2004 in the Millingerwaard [52]. The dataset consisted of 13 sample
312 plots of 20x20 m in the forest area, which were selected following a random sampling scheme with a
313 minimum of 20 m distance from each other. Each plot was set up according to the VALERI
314 (Validation of Land European Remote Sensing Instruments) protocol [53] and consisted of 12
315 measurement points per plot. At each point within the plot one measurement in 180° upward direction
316 and one measurement in 180° downward direction were taken with the hemispherical camera. The
317 hemispherical photographs were processed with use of the neural network based software CAN_EYE
318 to calculate the gap fraction and to derive the clumping factor and true LAI values [54]. The validation
319 dataset from 2005 consisted of 16 sample plots of 20x20 m with more or less homogeneous vegetation
320 cover in herbaceous, shrubs and forest vegetation. The sample plots were also set up according to the
321 VALERI protocol. The effective LAI was estimated with use of hemispherical photography and
322 subsequently corrected into true LAI values with use of the average clumping index per plant-
323 functional type from TRAC (Tracing Radiation and Architecture of Canopies) measurements and
324 woody-to-total area ratio from the hemispherical photographs [55].

325

326 *2.5 Upscaling of the method*

327

328   Finally, the methodology was upscaled to all floodplains within the complete river section of the
329 Gelderse Poort nature reserve (figure 1). RT models are not limited to site or sensor-specific
330 dependencies [56] and can therefore be applied to larger floodplain areas without having to
331 compromise on the retrieval quality. First, a land cover classification was made, based on the same
332 training dataset which was used for the Millingerwaard. Thereafter, FLIGHT model inversion was

333   applied per vegetation class for the Gelderse Poort to derive LAI values. Because of the class-based
334   inversion approach and the broad range of simulations present in the LUT for each vegetation class,
335   covering a large variety of plausible canopies, no additional adjustments had to be made to upscale the
336   same methodology to the larger floodplain area. Finally, in view of applying the class-based model
337   inversion approach to images from any imaging spectrometer, the whole methodology has been
338   implemented into a Matlab-based graphical user interface (GUI) toolbox called ARTMO (Automated
339   Radiative Transfer Models Operator) [57]. Hence, with ARTMO LAI maps can be obtained in a
340   semiautomatic way thereby taking the distinct nature of different land cover classes into account.

341

342   **3. Results**

343   *3.1 Classification*

344

345   The classified land cover map of the CHRIS nadir image for the Millingerwaard is presented in
346   figure 3b and has an overall accuracy of 68% and a kappa coefficient of 0.56 (table 3). Notably, most
347   misclassifications occurred between the 'grasses and herbaceous vegetation' and the 'herbaceous and
348   low woody vegetation', because the spectral characteristics of these classes have similarities and
349   mixing of different vegetation types occurred in the pixels (~17 m) of the CHRIS image. When
350   merging these two classes, the overall accuracy improved to 73%. The largest part of Millingerwaard
351   was covered by grasses and (low and higher) herbaceous vegetation. Some parts of the river
352   floodplains have recently been excavated and consisted of bare soil. Shrubs and softwood forest
353   surrounded the lakes. Some pieces of land in the eastern part with a rectangular shape and
354   homogeneous land cover represented arable land and agricultural grassland. The remaining part of the
355   area had a heterogeneous land cover with transitions between land cover types on the pixel-level which
356   is characteristic for a natural river floodplain ecosystem.

368   *3.2 Vegetation class based angular LAI retrievals*

369

370   LAI maps were generated through model inversion for the vegetation cover classes of 'herbaceous',

371   'shrub' and 'forest' vegetation within the Millingerwaard study site. LAI results for herbaceous, shrub

372   and forest vegetation were combined into a single map for each viewing direction (figure 4 [left]).

373   White parts in the maps represent areas that were not included in one of the three vegetation classes.

374   Large variation in retrieved LAI values could be observed within all the three classes in the river

375   floodplain area, which reinforces the significance of quantifying density at the pixel level. Largest LAI

376   variability was obtained in the -36º VZA, closely followed by the nadir direction, whereas the variation

377   of the inverted values was considerably lower for +36º VZA. Spurious high LAI values between 8 and

378   9 occurred in several fields and along the dikes. Due to their rectangular shape and homogeneous land

379   cover (figure 3) it could be deduced that these dense vegetated areas are probably related to intensively

380   managed agricultural grasslands. Similar orders of magnitude were observed along the dike in the

381   south of Millingerwaard, also due to agricultural use (grassland or maize). These agricultural areas are

382   excluded in further analysis. The generated histograms show the LAI distribution of the river

383   floodplain for the three viewing angles (figure 4[right]). From these histograms it can be observed that

384   nadir failed to identify pixels with very low LAI (<1), which are present over the sandy river banks. In

385   case of -36 VZA, LAI values ranged between 0.3 and 6 for the shrubs and herbaceous areas. Large

386   variations were obtained within the herbaceous vegetation class west of the lakes. Peaks in LAI

387   indicated the spatial pattern of shrub encroachment, where the highest values belonged to the fast

388   growing shrub *Crataegus monogyna* (hawthorn). Also the shrub class around the lakes showed great

389   variation in LAI. This concerned mainly *Salix* (willow) species which vary in density and height. The

390   forest class, which was simulated in 3D, yielded LAI values within a narrow range, between 5 and 7.

391   When validating the LAI results, it can be observed from the scatter plots (figure 5) that the nadir

392   and -36º VZA performed alike, with a somewhat better RMSE accuracy for -36º VZA. The RMSE

393   accuracies were 1.05 for -36º VZA and 1.23 for nadir respectively. For both viewing angles the

394   retrieved LAI values were overall closely positioned to the 1:1-line. The retrieved LAI values fell

395   within the same range between 2 and 7 as the LAI values obtained with the hemispherical camera

396   (figure 5). Though, it has to be noted that over the pixels labelled as forest hardly variation in LAI was

397   detected. Conversely, the +36º VZA led to considerably poorer accuracies (RMSE: 2.63), suggesting

398   that this viewing angle leads to suboptimal retrievals.

399   Another way of evaluating the performances of the LAI retrievals is inspecting the RMSE residuals,

400   which were mapped in figure 6 [left]. Although no validation *per se*, these RMSE maps can give us a

401   better spatial understanding of the success of the inversion process. When comparing the viewing

402   angles it can be noted that nadir and -36º VZAs performed alike, while forward scatter +36º VZA had
403   more difficulty with the inversion. The latter not only led to overall poorer residuals but also delivered
404   considerably more patches with very poor retrievals (dark red spots). This implies that some degree of
405   mismatch between actual spectra and the simulated spectra took place. It suggests that either FLIGHT
406   was not well able to represent the complex shadowing effects in this direction or that a more accurate
407   atmospheric correction regime is needed at this angle. The RMSE maps also suggested that there were
408   no indications that one vegetation class performed worse than the other classes; the image was
409   consistently inverted with some patches (dark red spots) of poorer residuals. These patches typically
410   emerged on landscape edges or on areas with high LAI retrievals. Finally, when looking closer to the
411   residuals at nadir and -36º, despite some patches of poor retrievals, -36º VZA showed slightly better
412   performances throughout the whole image. This can also be observed in the histograms of the residual
413   maps (figure 6 [right]), where the -36º VZA led to considerably more pixels with very low RMSE
414   values (very left part of histogram).

415   **Figure 4.** LAI maps (left) and derived histograms for LAI<8.5 (right) of Millingerwaard for the
416   backward scattering direction (-36° VZA) (top), the nadir direction (middle) and the forward scattering
417   direction (+36° VZA) (down), derived with FLIGHT model inversion.

418
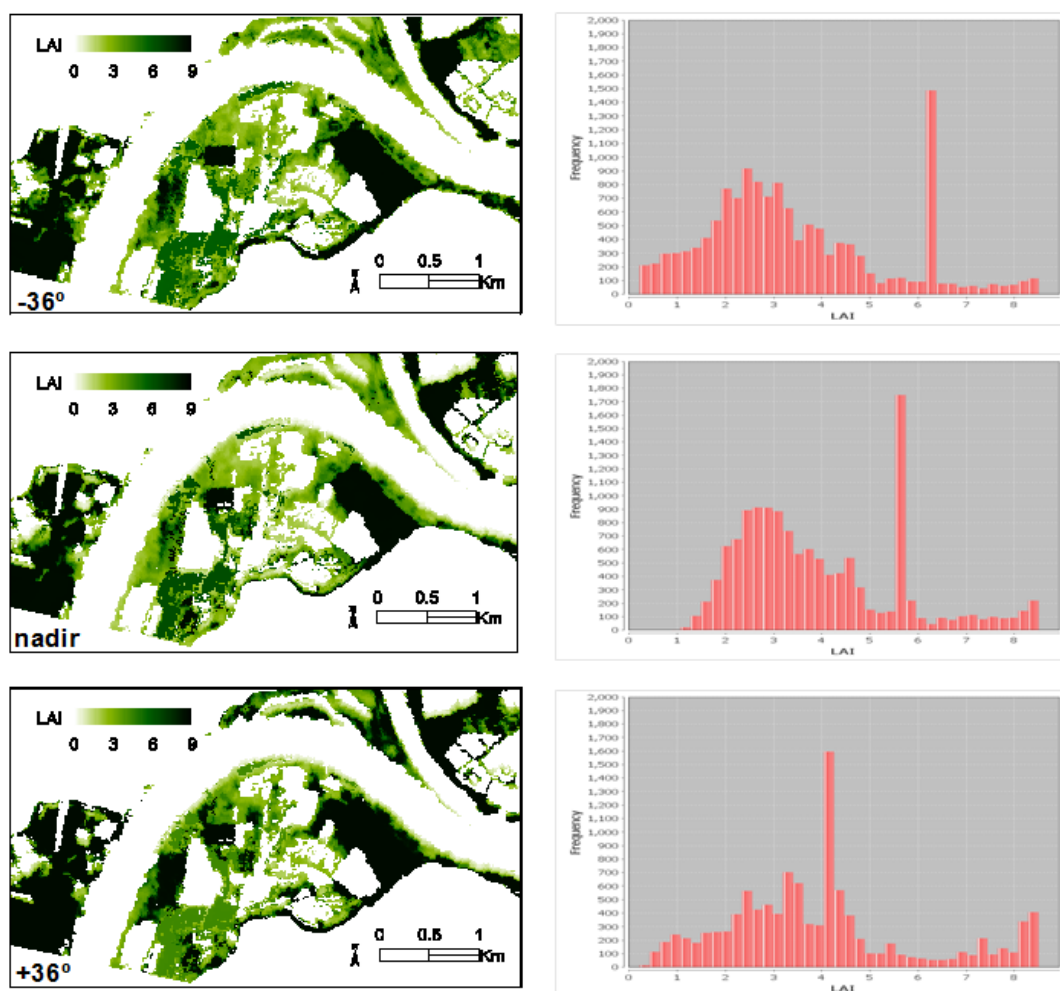

Figure 5. Validation results of the estimated LAI obtained with FLIGHT model inversion, plotted against the measured LAI values obtained with the hemispherical camera for the backward scattering direction (-36° VZA), the nadir direction and the forward scattering direction (+36° VZA).
Figure 6. Maps of minimum RMSEs for LAI retrievals (left) and derived histograms for <8.5 (right) of Millingerwaard for the backward scattering direction (-36° VZA) (top), the nadir direction (middle) and the forward scattering direction (+36° VZA) (down), derived with FLIGHT model inversion.
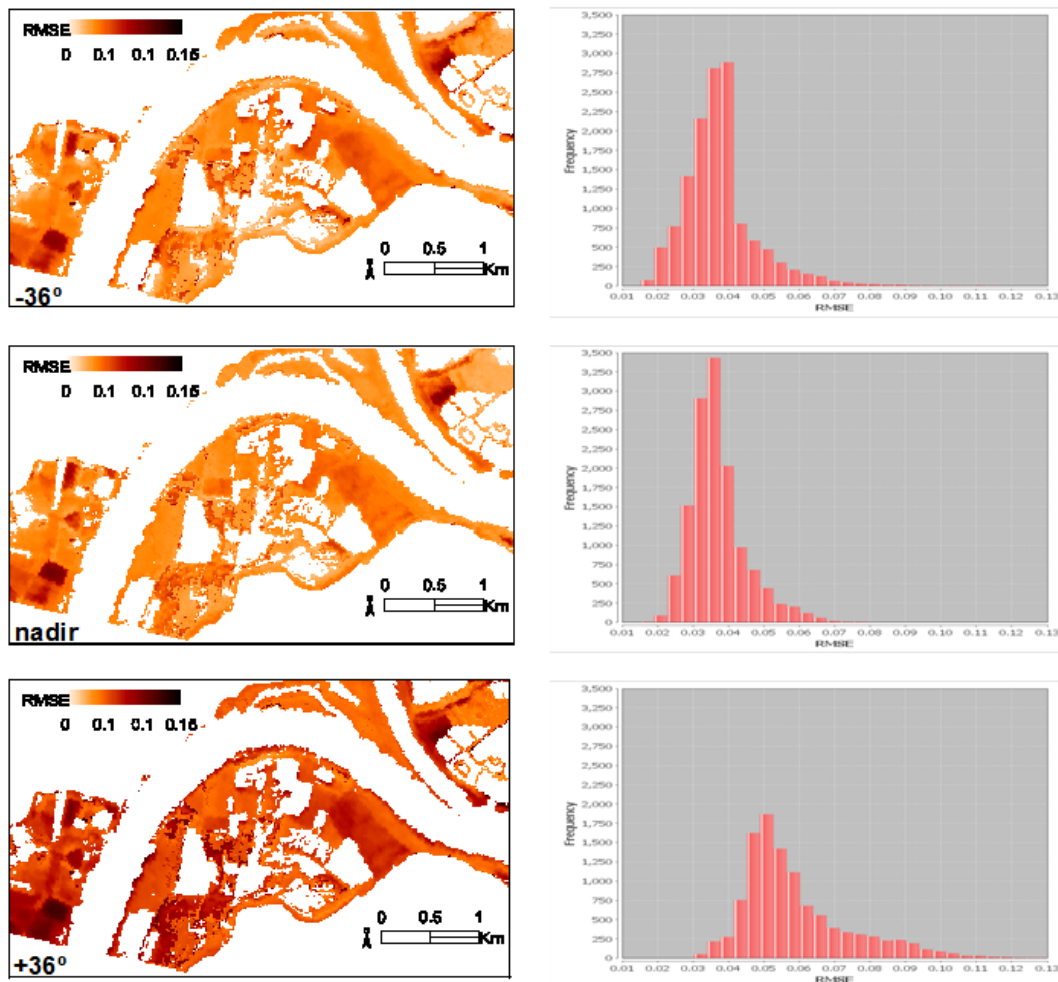

430   *3.2 Upscaling LAI maps to the larger floodplain 'Gelderse Poort'*

431

432   To demonstrate the portability of the class-based model inversion, the complete methodology was

433   applied to the larger floodplain area of the Gelderse Poort nature reserve. This resulted first in a land

434   cover map (figure 3a) and subsequently LAI maps for the three viewing angles for this area. The land

435   cover map reveals that most natural vegetation is present in the southern part of the land cover map.

436   The Millingerwaard floodplain is located here, but the landscape is also characterized by patches of

437   semi-natural grasslands, shrubs, bare soil and lakes and agricultural fields. To the North, the landscape

438   is dominated by agricultural crops and grasslands. These parts have not yet been subject to the natural

439   management regime. The map formed the basis for the class-based LAI retrieval. Figure 7 shows as an

440   example of the LAI map for the -36º VZA, the viewing angle that was best validated and where most

441   variability was perceived. Generated LAI values over the larger floodplain were within the same range

442   as over the Millingerwaard. Large LAI variability can be observed in the more natural areas, especially

443   in the South and South-eastern part of the map, but also in some parts along the river in the centre and

444   North of the map. More northwards, where more agricultural fields were present, areas of high LAI
445   values suggest that these parcels consisted of homogeneous agricultural vegetation cover, such as

446   mature maize fields.

447

448   **Figure 7.** LAI map and histogram for the backward scattering direction (-36˚ VZA), derived with
449   FLIGHT model inversion after upscaling to the Gelderse Poort area.

450
451

452 **4. Discussion**

453

454   New methods are required to automate approaches and streamline the tedious process of hydraulic

455 roughness calculation for vegetation in river floodplains [14]. The overall goal of this study was to

456 develop and test a methodology for spatially-explicit estimation of vegetation density using data from

457 pointable EO spaceborne platforms. In the next sections, first the characterization of vegetation density

458 in terms of LAI for a river floodplain, and next the proposed approach of customized model inversion

459 against pointable, imaging spectroscopy data will be discussed in more detail. Finally, the discussion

460 will be closed with recommendations towards operational river floodplain monitoring.

461

462 *4.1. Vegetation density characterization*

463

464   LAI is one of the main biophysical variables that can be derived from space [15]. At the same time,

465 LAI can be considered as an important proxy of vegetation density, e.g. for the calculation of hydraulic

466 roughness of river floodplains. Specifically the vegetated areas with high LAI have potential to

467 generate a high accumulation of biomass, and are most critical for the estimation of the hydraulic

468 conductivity of the floodplain. For these areas removal of vegetation under the Cyclic Floodplain

469 Regime could be considered [13]. Moreover, deriving LAI from pointable observations may be

470 beneficial compared to conventional nadir observation because of the ability of controlling the

471 contribution of shadowing effects.

472   Our results show a prominent spatial and angular variability in LAI values within the studied

473 floodplain across the -36°, nadir and +36° VZAs (figure 4). When comparing LAI retrievals from the

474 different angles, it appeared that the -36° VZA demonstrated largest variability and best retrieval

475 performances. Particularly subtle LAI variations in case of low LAI were best detected in this viewing

476 configuration (figure 4[top]). An explanation for this observation is that the -36° VZA approached the

477 hotspot most closely, which implies the least influence of shadowing effects and therefore an enhanced

478 richness of subtle variations in reflectance [23,58]. Such enhanced subtleties are assumed to be in a

479 way related to an increased sensitivity towards structural variables [59,60], which makes the viewing

480 angle closest to the hotspot of specific interest.

481   Slightly less accuracy and variability in LAI retrievals was observed in nadir VZA (figure

482 4[middle]). The lowest accuracy in LAI retrievals occurred at +36° VZA (figure 4[bottom]). In this

483 direction most of the leaf surfaces are shaded, thereby suppressing variations in reflectance and thus

484 sensitivity in assessing foliage density. Similar results but for a coarser resolution of 275 m were

485 obtained with the usage of multi-angular broadband MISR data [61,62]. These studies underlined that

486   the surface anisotropy signatures varied with sun-target-sensor geometry as well as with seasonality

487   due to changes in canopy composition and structure. Other studies [63,29] found increased sensitivities

488   to vegetation structure and reduced understory effects in off-nadir viewing angles when compared to

489   mono-directional nadir data. This evidence of increased sensitivity to vegetation structure supports the

490   observation that the LAI retrievals from -36° VZA lead to superior results when compared to the

491   conventional nadir VZA. However, as our results showed that the differences between -36° and nadir

492   direction were rather small, which suggests that nadir observations are still a valid option.

493

494   *4.2. Combined classification and radiative transfer modelling approach*

495

496   Vegetation classification prior to model inversion proved to be a vital step for proper retrieval of

497   biophysical parameters in heterogeneous or patchy landscapes. Effectively, one of the main drawbacks

498   regarding the usage of RT models is the poor representation of the ensemble of vegetation structural

499   variables and optical properties present in the field (e.g., [64-66]). RT models are typically

500   parameterized for a specific land cover type, e.g., crops, forest, grassland, thereby restricting model

501   inversion to this specific land cover type. However, in patchy or heterogeneous landscapes, such as

502   river floodplains, it cannot be assumed that model parameterization for one vegetation type is valid for

503   the whole landscape. In this respect, the proposed 1D/3D parameterization (along with distinct optical

504   properties) per vegetation class ensures a more accurate representation of the landscape heterogeneity.

505   From the generated LAI maps it can be observed that the three proposed classes of herbaceous, shrubs

506   and forest proved to be valid within the floodplain of the Millingerwaard. Though, at the same time the

507   fact that spurious high results appeared over agricultural (maize) areas in the larger region suggests

508   that these areas fell not within the range of simulations that were parameterized according to the

509   'herbaceous' class. For improved LAI retrievals it would therefore be wise to consider these areas as a

510   new class and parameterize the RT model accordingly.

511   A difficulty of vegetation class-based inversion is that it relies on a classified map of sufficient

512   quality. Apart from the enriched information content for retrievals of vegetation density properties,

513   pointable data can also enhance the classification process itself. For instance, here ROIs were

514   identified with great precision because in certain PC-band combinations of the stacked layers of the

515   three viewing angles the different classes had bright, distinctive colours. However, the potential of

516   pointable data in the classification process has not yet been exploited to the fullest. In this study,

517   classification was performed on the CHRIS nadir image only. Owing to the advantages of the multi-

518   dimensionality of CHRIS, pointable observations may also be used as input into the classification

519   method. For instance, [67] found that differences in classes were more evident in multi-angular band

520 compositions than in RGB true colour compositions. By using stacked layers of all multi-angular
521 CHRIS observations as classification input instead of relying on solely the nadir image they improved
522 the neural network classification results with 7%. Several other studies demonstrated the strength of
523 multi-angular information in improving land cover classification [68,23]. The latter authors improved
524 the classification accuracy with a combination of nadir and off-nadir data, because as such they were
525 better able to catch the canopy characteristics. Further, in a study by [69] nadir classification accuracy
526 was improved by using additional anisotropic information derived from reflectance ratios of different
527 viewing angles from CHRIS data, enhanced with PCA. Given these examples, a next step would be to
528 elaborate on a more standardized protocol using data from pointable imaging spectrometers so that
529 classifications and vegetation density retrievals can be realized in a more operational way. Besides, a
530 more precise land cover map as base map may also lead to more accurate LAI retrievals. Apart from
531 the here applied Maximum Likelihood classification numerous alternative classifiers exist which may
532 be more successful in heterogeneous areas, such as unsupervised classifiers, support vector machines,
533 fuzzy classifiers, neural networks (see review [70]). Finally, when moving towards operational use,
534 additional gain in accuracy can be achieved through *i*) synchronizing acquisition of field data with the
535 satellite overpass , and *ii*) fine-tuning parameterization of vegetation classes for improved class-based
536 model inversion.

538 *4.3. Towards space-based river floodplain monitoring*

540   Overall, this study profited from the availability of pointable hyperspectral CHRIS data and the
541 advantages of the RT approach. With a physical model, the specific background and vegetation
542 reflectances for each vegetation type were taken into account, which makes LAI retrievals more
543 accurate [33]. Because no additional *in situ* calibration data sets were needed for this RT approach, the
544 class-based model inversion was easily applied to the larger area of the Gelderse Poort, which
545 demonstrated the suitability of this approach to map the floodplains of the whole river catchment.
546   While CHRIS data were successfully inverted into vegetation density variables, it should
547 nonetheless not be forgotten that PROBA is not an operational spacecraft but was designed as a
548 technology demonstrator. In fact PROBA was initially intended as a one year mission [28]. Currently
549 no new multi-angular imaging spectrometer missions are planned to be launched. Conversely, there is
550 a growing trend to design a new generation of imaging spectrometers with pointable capabilities.
551 EnMAP is such an example with ± 30º off-nadir pointing capabilities that aims to deliver operational
552 data products [71]. In addition, another upcoming superspectral spaceborne system, named Vegetation
553 and Environmental New micro Spacecraft (VENµS), also has pointable capabilities within the range of

554 30º along and across track and will be launched in 2013 [72]. For both of these sensors, vegetation
555 monitoring of both crops and natural vegetation will be an important application domain. Our results
556 support that off-nadir images benefit to the retrieval of vegetation density parameters and may
557 therefore be of specific interest in view of these upcoming pointable sensors. Further study is required
558 to investigate the viewing angle effect on RT model inversion of vegetation properties, including the
559 consequences for changing temporal resolutions.

560   Regardless of progress with respect to refined LAI mapping, eventually one single hydraulic
561 roughness parameter is required by the river manager. It remains to be investigated whether LAI alone
562 would suffice for deriving hydraulic roughness estimates or if additional information is required.
563 Therefore, a next research step would be to explore LAI outcomes in conjunction with other relevant
564 structural variables that can be derived from space such as fractional vegetation cover and vegetation
565 height [13]. Straatsma and Baptist [12] used both spectral and altimetry airborne data sets to estimate
566 roughness input parameters such as vegetation height and vegetation density, and subsequently used
567 these data as input into a hydrodynamic model to compute hydraulic roughness values of a local river
568 floodplain. When having a vegetation class map of the larger area available, class-based inversion of
569 LAI can be easily upscaled to a whole river catchment area. Compared to the traditional ecotope
570 approach spaceborne optical data offer a standardized, spatially-explicit and repeatable methodology
571 that can cover complete river catchments with high spatial detail. Benefitting from the enriched
572 information present in the backscatter direction, it is beyond doubt that operational pointable sensors
573 (e.g. EnMAP, VENµS) will play an important role in monitoring programmes. Given this all, further
574 research efforts should lie in elaborating on the compatibility of hydrodynamic models with
575 spaceborne-derived input variables.

576

577

578 **5. Conclusions**

579

580   Pointable imaging spectrometers possess advanced capabilities to observe vegetation under a
581 preferred viewing angle. The use of pointable CHRIS images for mapping vegetation density of a river
582 floodplain in the Netherlands was investigated. The spatial distribution of leaf area index (LAI) was
583 estimated from CHRIS data using the ray tracing model FLIGHT. The CHRIS nadir image was first
584 classified into three distinct vegetation classes ('herbaceous', 'shrubs', 'forest') that formed the basis
585 for class-based model inversion. By configuring FLIGHT per vegetation class a more accurate
586 representation of the heterogeneous nature of a river floodplain can be achieved, e.g., herbaceous and
587 shrubs were simulated in 1D mode while forest was simulated in 3D mode. LAI values were

588 subsequently pixelwise and class-based derived through model inversion, and this for each view zenith
589 angle (VZA: -36°, nadir, +36°) separately. LAI retrievals matched best with validation data at -36°
590 backscatter direction, which is the viewing angle that was positioned near to the solar position, closely
591 followed by nadir VZA. Also most LAI variability was observed in these two viewing angles. This
592 suggests that in absence of pointable observations nadir-based observations would be perfectly
593 appropriate for vegetation density monitoring applications. The forward scatterer +36° VZA led to
594 considerably poorer retrievals and is not recommended to be used for quantifying vegetation density.
595 The here proposed methodology has been implemented in a software package ARTMO. With ARTMO
596 LAI maps over larger areas can be generated in a semi-automatic way, while at the same time the
597 heterogeneous nature of the landscape and the viewing configurations of the sensor have been properly
598 interpreted. This opens opportunities in view of upcoming operational sensors with pointing
599 capabilities such as EnMAP and VENμS.
